(54) Title: DIRECTIONAL DIFFUSER

(57) Abstract: A diffuser is disclosed which transmits or reflects incident light into a specific range of angles. In a preferred embodiment, this light is uniformly scattered throughout a cone of angles. The diffuser consists of two parts. The first part diffracts or reflects light into a specific offset angle. The second part, in the preferred embodiment, uniformly scatters the light through a range of angles, which is centered on the offset angle. The diffuser have utility in applications such as screens for wrist watches, computers, calculators, and cell phones.

DIRECTIONAL DIFFUSER

FIELD OF THE INVENTION

5 The present invention relates generally to an optical diffuser and method for making the same, and more particularly to an optical diffuser having a high diffraction efficiency, broadband response and cost effective method of producing the same.

BACKGROUND

10 Reflective diffusers are required for many applications, including liquid crystal displays, to enhance their viewability. Often these diffusers, placed behind the liquid crystal element, are simply roughened reflective surfaces. These reflectors utilize no back lighting, but instead rely on the scattered reflection of the ambient light. Unfortunately, light scattered from these devices is centered around the glare angle, which is in direct line-of-sight with the
15 undesirable reflections from their front surface. Furthermore in many applications, such as computer screens, and perhaps watches, the preferred orientation of the device is one for which viewing at the glare angle is not optimum. The situation can be improved by using holographic diffusers which allow the reflection angles of interest to be offset, so that the maximum brightness from the diffuser falls in a preferred viewing angle which is different
20 from that of the glare. One type of holographic diffuser that is sometimes used is the reflective, "surface-relief" hologram. This hologram has the advantage over other types in that if the ambient light is white, the reflected diffuse light is also white. Another advantage of the surface-relief hologram is that embossing can reproduce it easily and inexpensively. A major disadvantage is that the surface-relief hologram can be inefficient. Only a relatively
25 small percentage of the incident light is diffracted into the desired viewing angles (typically less than 30 degrees)

A non-holographic diffuser, when coupled with a reflective focusing screen, uses randomly sized and randomly placed minute granules, which are created by interaction of solvent particles on plastic surfaces (See U.S. Patent No. 3,718,078, entitled, "Smoothly
30 Granulated Optical Surface and Method for Making Same"). These granules are dimples of extremely small magnitude (one half of a micron in depth), which reflect incident light more or less uniformly over a restricted angle. However, the angles of reflectance are very small,

WO 02/10803

PCT/US01/41559

- 2 -

usually about + or - 3 degrees, and the light reflected from them is here again at the glare angle.

A second kind of off-axis, holographic diffuser in common use today is the volume reflection diffuser, which can be provided by Polaroid Corporation of Cambridge

- 5 Massachusetts. With volume holograms, fringes that give rise to the diffuser reflection are distributed throughout the volume of the material, unlike the surface reflection concept of the "surface-relief" holograms. Because of this, light of a wavelength that is characteristic of the spacing distance between the fringe planes is resonantly enhanced over all other wavelengths. Thus, the reflected light is highly monochromatic. For example, if the spacing is
10 characteristic of green, then green will be the predominant reflected color for incident white light. Unlike conventional embossed holographic diffusers, the reflection can be extremely efficient, although only over a narrow wavelength band. As a result, the surface-relief hologram can appear dim because most of the incident white light falls outside of this select band. Further processing can increase the bandwidth, thus increasing the apparent brightness,
15 but the resulting diffuser still has a predominant hue, which is in most cases undesirable. In any event the bandwidth is still somewhat restricted, thus limiting the reflection efficiency.

Therefore, an unsolved need has remained for a diffuser having a high diffraction efficiency, broadband response and cost effective manufacture, which overcomes limitations of the prior art.

20

Summary of the Invention

- In an embodiment of the present invention as set forth herein is a blazed diffuser, which includes a reflective surface having a sawtooth structure. The sawtooth structure includes a series of contiguous wedges, each of which reflects incident oblique light into a beam which is more or less normal to the gross surface of the device. This wedge structure may be regarded as simply an off-axis mirror if the wedge spacing (period) is much larger than the wavelength. Superimposed on this wedge surface is a second structural component, which by itself diffracts incident light normal to its surface into rays, which constitute only those over a restricted narrow angle (e.g. + or - 15 degrees). This angle is specified as that
25 which is desired for a particular application. In an embodiment, this second surface shape is one that uniformly scatters an incident ray throughout the viewing angle. Such a structure gives a so called "flat top" scattering. When these two structures are superimposed, light
30

WO 02/10803

PCT/US01/41559

- 3 -

incident from a predetermined angle which is dependent on the wedge angle, is uniformly scattered throughout a specified range of viewing angles with a high degree of efficiency. Almost all incident light is utilized and efficiencies approaching 100% for all visible wavelengths are possible.

5 In another embodiment, a blazed diffuser is made entirely by optical, holographic means, and it can be fabricated in such a way that the broadband spectral colors are properly mixed so that the diffracted light appears white. The recording for this diffuser is done in two primary ways. The first is by recording directly from a predetermined diffuse surface, and the second is by copying from a volume diffuser into a surface diffuser.

10

BRIEF DESCRIPTION OF THE DRAWINGS

The foregoing and other objects of this invention, the various features thereof, as well as the invention itself, may be more fully understood from the following description, when read together with the accompanying drawings in which:

15 Figs. 1A, 1B and 1C show a number of embodiments of the diffuser in accordance with principles of the present invention;

Figs. 2A, 2B, 2C, 2D, 2E and 2F show a number of embodiments of reflective surfaces associated with the embodiments of the diffuser shown in Figs. 1A, 1B and 1C;

Fig. 3 shows the flat top diffraction profile of the surface of Fig. 2E;

20 Fig. 4 shows the diffraction profile of a surface which approximates that of Fig. 2E;

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

10 The present invention provides an improved diffuser having a high diffraction efficiency, broadband response and method for making the same.

Referring to Fig. 1A, an embodiment of the present invention as set forth herein comprises an improved diffuser including a reflective surface. The reflective surface may include a periodic wedge structure 1, as shown in Fig. 1A, which reflects incident light 2 so 15 that incident light 2 impinges on its surface 3 from an oblique angle, θ , into rays 4 which are approximately normal to its surface. These reflected rays 4 are contained within a small angular spread if the period p of the wedge is much greater than the wavelength of the light, λ . It is essential that the wedge angle ($\theta/2$) for the surface 3 in Fig. 1A, be selected for the particular application (e.g. $\theta/2 = 15^\circ$) and that the period p be large compared to the 20 wavelength (typically $p > 100 \lambda$). However, a period that is too large (> 100 microns for example) may be visually annoying. If p is not much larger than λ , then incident light is scattered over other angles than that normal to the surface, as predicted by diffraction analysis. Furthermore the angle of scattering is then wavelength dependent, a feature that tends to detract from a desirable white diffusion pattern.

25 Referring further to Fig. 1B, the diffuser further includes a second structure 5, which is disposed on the reflective surface. The second structure uniformly reflects incident rays across a prescribed angle, α . The surface 6, which is shown in Fig. 1C, accepts an incoming oblique beam and scatters it uniformly over a range of angles, α . The scattered beam is centered on the normal to the structure with high efficiency. The geometry of the second 30 structure 5-or scattering structure, may itself be periodic with period q , which is smaller than,

WO 02/16803

PCT/US01/41559

- 5 -

equal to, or slightly larger than the wedge period p. Such examples of these structures are shown in Fig. 2.

There are a variety of surface shapes that may be used for these structures. In the present embodiment, a shape for an element of the resulting combined surface can be

5 described by the simple equation:

$$s(x) = a x^2 + bx, \quad (1)$$

where $s(x)$ is the height of the surface and x is the coordinate on the surface, and an element
10 is defined to span only one peak of the structure as is shown by the dimension q in Fig. 2.

The second term of equation 1 represents the tilted flat surface on wedge 3. The first term is that of a quadratic, or parabolic reflector, either positive or negative.

Simple microlens arrays may be approximated by periodic, two-dimensional parabolic surface arrays and as such have been used successfully to create flat top diffraction patterns,
15 i.e., uniform on-axis reflection (or transmission) over a specific range of angles.

Theoretically, a plane wave of incident light is uniformly reflected from a periodic surface throughout a specific range of angles because it has a constant second derivative.

In general, the diffraction from any reflective phase surface element, $s(x)$, can include:

20

 $q/2$

$$f(\gamma) \approx (1/q) \int_{-q/2}^{q/2} \exp [2i s(x) k] \exp [-i kx \gamma] dx \quad (2)$$

where γ is the reflection angle (radians), and $k = 2\pi/\lambda$. For example, inserting for $s(x)$ the
25 parabolic function of equation 1, minus the wedge (sawtooth) portion, equation 2 yields

- 6 -

$$f(\gamma) \sim \exp [ik\gamma^2/8a] \int_{t_1}^{t_2} \exp (-i\pi t^2/2) dt \quad (3)$$

5

$$\text{where } t_1 = -\sqrt{2a/\lambda} q + \sqrt{1/2a\lambda} \gamma$$

$$\text{and } t_2 = +\sqrt{2a/\lambda} q + \sqrt{1/2a\lambda} \gamma$$

10

The integral in equation 3 is known as the Fresnel integral.

A typical plot of the amplitudes of the diffraction function of equation 3, is shown as the dashed curve 7 of Fig. 3. Such curves are derived by data plotted in cornu spirals, which are a convenient representation of these Fresnel integrals. As the size q of the element increases, the undulations evident at the extreme angles are reduced and the curve approaches the flat top distribution, which is desired for a preferred embodiment. However, this second component of the diffuser structure is periodic, the periodicity of which is q . For a periodic structure, the angular reflection distribution is punctuated by distinct peaks, the distance between which is proportional to the wavelength, λ , but is inversely proportional to the element size q . These peaks, which represent the various orders diffracted by the structure, are centered on the solid lines 10 shown in Fig. 3. The presence of these periodic peaks need not be detrimental to the diffuser visibility if the period q is large compared to the wavelength, in which case they will be very close together, or if the incident light is specularly broad or spatially diffuse, thus obscuring them. For the examples in Figs. 2A and 2B, the elements 11 and 12 are as large as that of the sawtooth, i.e., $q = p$, which is an extreme, and perhaps a desirable case, because it also reduces the undulations in the envelope (the dashed curve) as discussed before.

For parabolic structures, the diffraction function for elements 9 and 12, shown in Figs. 30 2B and 2D, is slightly different than that represented by equation 3 due to the inverted parabolic function. The applicable equation for that surface is

- 7 -

$$t_4 \\ f'(\gamma) \sim \exp [i k \gamma^2 / 8a] \int_{t_3}^{t_4} \exp (-i \pi t^2 / 2) dt \quad (4)$$

where $t_3 = -\sqrt{2a/\lambda} q + \sqrt{1/2a\lambda} \gamma$

and $t_4 = +\sqrt{2a/\lambda} q + \sqrt{1/2a\lambda} \gamma$

10

The function f' is the complex conjugate of f (i.e., $f' = f^*$), a result that is evident from Fourier analysis, and so the amplitude of f' is also represented by the dashed curve 7 of Fig. 3. Here again, a periodic structure as shown in Fig. 2D, results in peaks represented by the solid lines 10.

15

The structures 13 and 14 shown in Figs. 2E and 2F combine the elements described by equation 3 and equation 4. After addition of suitable requisite phase terms (to account for lateral shifts and pedestal phase functions), these surface components, in the absence of the sawtooth component, give diffraction functions $f(\gamma)$

20

$$f(\gamma) \sim \Re \{ \exp [i k \gamma / 2 + i k a^2 / 2] f(\gamma) \} \quad (5)$$

where the symbol \Re refers to the 'real part'.

25

Because of the additional phase terms in equation 5, the dashed curve 10 of Fig. 3 represents the maximum diffraction that is achieved. Furthermore, peaks occur in this curve at half the distance of those for the cases discussed so far, since the period of this combined structure is now $2q$ versus q previously.

The surface shown in figure 2G is particularly interesting. Each element of figure 2A alternates with its inversion shown in Fig. 2B to produce a surface without discontinuities.

30

Each element of width P , is an offset parabola when equation (1) is applied.

WO 02/10803

PCT/US01/41559

- 8 -

A surface which approximates the undulating parabolic surface of Fig. 2E (disregarding the sawtooth or wedge) is that which is represented by a sine or cosine function. Such a function can be constructed from the surface relief etching of two interfering, coherent beams. A function describing such a surface can include:

5

$$s(x) \approx c \sin(\pi x/q) \quad (6)$$

where $2c$ is the peak-to-peak excursion of the function, which is periodic in $2q$. Inserting this function into equation 2 results in the diffraction function

10

$$f(\gamma) \approx \int_{-q}^q \exp[2i k c \sin(\pi x/q)] \exp[-i k x \gamma] dx \quad (7)$$

15

whose solution is

$$f(\gamma_m) \sim J_m(2 k c) \quad (8)$$

where J_m is the m^{th} order Bessel function of the first kind, m is an integer, and $f(\gamma_m)$ represents the amplitude of the diffracted (or reflected) beams at the discrete angles of $\gamma = m\lambda/p$. In Fig. 4, discrete values of $|f(\gamma_m)|^2$, for example 15 and 17, are plotted for the case in which the period $2q$ equals 38λ , and the angular spread is approximately ± 15 degrees. As can be seen in Fig. 4, the profile 16 is not flat-topped, but peaks at specific angles (17 in Fig. 4). Such peaks tend to be reduced as the period, $2q$, increases with respect to the wavelength, and a reasonable approximation to a flat top angular distribution is obtained.

Another method of producing a parabolic surface structure holographically is by the coherent interference of three laser beams in a layer of photoresist. If the sources of expanded light from each of the beams are arranged such that each source is approximately at the apex of an equilateral triangle, then the developed pattern in the photoresist will consist of a close-packed honeycomb array. By using suitable nonlinear etching characteristics of the photoresist, each honeycomb depression will develop in the shape of a paraboloid.

WO 02/10803

PCT/US01/41559

- 9 -

While the specific examples discussed so far relate to the reflection of incident light from a surface in air (i.e., $n = 1$), the analysis also applies to cases in which the light is reflected from a surface that is covered, for example, by a plastic overcoating. In an embodiment, a reflective diffuser is provided, which includes a reflective surface that is embossed into the underside of a plastic sheet. In this embodiment, slight modifications to the analysis must be made, mainly in an alteration of the depth of the structure. (In equation 2, for example, $s(x)$ becomes $n s(x)$, where n is the index of refraction of the plastic). Also certain modifications would enable these devices to be used as transmission diffusers, rather than reflection diffusers.

Construction of surfaces discussed herein, and examples of which are shown in Fig. 1, may be carried out by a number of processes. For well defined periodic functions like those shown in Fig. 1, the surfaces can be formed by micro-machining or laser etching (e.g., MEMS processes). Alternatively the surfaces can be formed in two separate steps, which includes a first step that produces a periodic sawtooth structure such as that shown in Fig. 1A. Such a strictly periodic structure can, for example, be machined with great precision and cast into a number of materials. A second step, which adds the diffusion, or second component, may be added, for example in the following way. After appropriately coating the periodic sawtooth structure with a photoresist layer, the diffusing structure may be created by exposure to appropriate optical patterns and suitable processing of the photoresist thereafter. These optical patterns may be generated as an interference pattern of a number of coherent beams (the sine wave for example), the three-beam honeycomb pattern as described above, or as a result of scanning the photoresist surface with a focused intensity modulated light beam (as with a laser). Alternatively the optical pattern to which the photoresist is exposed may be a random function resulting, for example, from a laser illuminated diffuser. Randomly diffuse functions whose angular diffraction envelope are flat-topped, are usually difficult to create, unless unique processes are used.

The randomness may be achieved for example by using small portions of the prerequisite parabolic surface, which are randomly positioned but which on the aggregate cause reflected light to be more or less uniformly reflected over the desired angle.

Another process, described in the following, is a direct holographic method. The structure created by this method is different than that discussed so far, in that the period p is of the same order as the wavelength, λ , and thus diffraction effects become important. Fig. 5

WO 02/10803

PCT/US01/41559

- 10 -

illustrates the results of scalar diffraction theory, in which curve 18 is the major diffracted order, and the diffraction efficiency approaches 100 % for the wavelength of interest. The step height h for the case shown in the Fig. 6 is equal to half the peak wavelength. For a central wavelength peak of 500 nm, the step height is thus 250 nm. This 5 efficiency curve assumes that the surface is an ideal reflector, providing 100% efficiency at the peak wavelength. The efficiencies are also high for the entire visible spectral range, roughly ranging from approximately 85% at 400 nm in the violet to approximately 75% at 700 nm in the deep red. For this reason 500 nm is generally chosen to represent the center of the visible spectrum, and the surface structure is designed to operate at this wavelength. Note 10 that there is a significant difference between the small scale structure represented by curve 18, and the diffraction (or reflection) from the surface 3 of Fig. 1A. In Fig. 1A, the step height is many wavelengths, resulting in a diffraction efficiency of close to 100% for all visible wavelengths.

The parameters of Fig. 5 are chosen for the case of an air interface bordering the 15 reflective sawtooth surface, similar to the situation shown in Fig. 1A. In the actual case, as with the situation of Fig. 1A, a preferable configuration is the coating of the surface with a protective layer, usually a clear plastic material 19 having an index of refraction, $n = 1.5$, as in Fig. 6. The tilt angle of the sawtooth 3 is chosen to provide an optimum viewing angle normal to the surface when light is incident at the proper offset angle, which for illustrative 20 purposes can be 30 degrees. The wedge angle, $\beta/2$, can be selected for the overcoated surface as shown in Fig. 6. Snell's Law, $\sin \theta = n \sin \beta$, for light passing from air with index 1 into a medium with index n , yields, for an entrance angle from air of $\theta = 30$ degrees, an exit angle of $\beta = 19.47$ degrees within the $n = 1.5$ surface. The wedge tilt angle is half this value, or $19.47/2 = 9.74$ degrees. The revised step height is $h = 250/n = 250/1.5 = 166.67$ nm. The 25 period p is calculated from the grating equation for normal incidence, $\lambda = p \sin \theta$, or $p = 500/\sin 30^\circ = 500/(1.5 \sin 19.47^\circ) = 1000$ nm = 1.0 micron.

One method of creating the periodic wedge is by recording the interference of two counterpropagating laser beams, 20 and 21 in Fig. 7, in a material 22 such as photoresist ($n = 1.7$). The equation for spacing between the interference planes, d , can include:

- 11 -

$$d = \lambda_o / [2n \sin (\theta_o/2)] \quad (9)$$

where θ_o is the half angle between the beams, and λ_o is the laser recording wavelength. Thus
5 the sine of the half angle is calculated in accordance with the following:

$$\sin (\theta_o/2) = \lambda_o / (2 n d) = 441.6 / [(2)(1.7)(169.11)] = .76803 \quad (10)$$

where a recording wavelength of $\lambda_o = 441.6$ nm from a He-Cd laser and an index of
10 refraction of $n = 1.7$ for photoresist have been used. The spacing, d , has been calculated as

$$d = h / [\cos (\beta/2)] = 166.67 / [\cos(9.74^\circ)] = 169.11 \text{ nm} \quad (11)$$

Thus equation 10 yields an angle between the beams of $\theta_o = 100.36^\circ$. The interference fringe
15 structure, 23, is shown in Fig. 7. This structure represents, after exposure, planes of maxima
and minima of exposure intensity. When the photoresist plate is immersed in developer,
etching or removal of the exposed photoresist proceeds from the top surface layer downward,
the most exposed layers being removed preferentially over the least exposed layers. Ideally,
20 the developer reaches the first zero exposure plane, which is represented by the dotted line 24
in Fig. 7. The fringe planes lying beneath this plane are not affected by the development.

The preceding discussion represents the types of calculations that must be made in
order to accurately form the fringe planes, and thus the sawtooth structure in a photoresist
material, which is ultimately used as a master copy for mass production. In an embodiment,
at least one of the beams, 20 and 21, in Fig. 7, can have some variation so as to create the
25 desirable angular diffusion.

If there were no diffuse component to the beam, then the light diffracted from the
sawtooth surface relief structure would, for incident white light, display all the spectral colors
from violet to red, although each would be viewable from a different angle. But controlled
diffusion is a requirement of this technology. Adding a diffuse component to obtain white
30 light means adding a variation in the grating period p or in the slope of the sawtooth, so that
all colors are mixed at the same diffraction angle. For example, taking the extremes of 400

- 12 -

nm for violet and 700 nm for red, the period p for these two colors is, respectively, $p = 400/\sin 30^\circ = 800$ nm (violet) and $p = 700/\sin 30^\circ = 1400$ nm (red) for the same diffraction angle of 30 degrees. If these extremes in the period for the visible spectrum are now present as part of the surface relief structure, then the diffraction angles for the design wavelength of 5 500 nm range from 38.68 degrees to 20.92 degrees, so that the total variation is $8.68 + 9.08 = 17.76$ degrees. Since the diffuser is nominally designed to operate at an angular spread of plus or minus 15 degrees from the main diffraction angle of 30 degrees (or a total angular spread of 30 degrees), there is sufficient angular variation for mixing the entire visible spectrum sufficiently to produce white light.

10 A method for making the diffuse structure is to use a split beam holographic setup and a predetermined diffuse surface. This method allows for flexibility in the range of recording angles. The method does, however, require the fabrication of a diffuse plate with the requisite viewing angles, which is inserted into at least one of the two recording beams. In one configuration, as shown in Fig. 8, requires the use of two prisms, 25 and 26, with a liquid 15 gate plate holder contacted by index matching liquid to both prisms. The calculated angles for beam 20 with respect to the normal, i.e., 49.56 degrees, is so large that it exceeds the critical angle, θ_c , which is $\theta_c = \arcsin(1/n) = \arcsin(1/1.7) = 36.03$ degrees. In the absence of a coupling medium, i.e., an air interface, all incident light would be at almost normal incidence to the face of the equilateral prism 25. Beam 20 enters the face of the opposite prism 26 such 20 that the angle of incidence to the photoresist material 22 from the $n = 1.5$ glass layer is equal to 34.61 degrees. In this case the fringe spacing and tilt angle in the photoresist are as required for the example above. Because the angle of incidence of beam 20 does not exceed the critical angle into photoresist, an alternative scheme allows beam 20 to enter the tank directly from air at 58.43 degrees. A third alternative is one in which the rectangular plate 25 holder tank is immersed in a large square tank filled completely with index matching liquid, thus eliminating the prisms altogether. While this latter method is relatively easy to implement it does require great care in allowing the index matching liquid to completely stabilize before making the recording.

Copying directly from a volume diffuser, as an alternative to the above, has many 30 advantages. One advantage relates to a volume diffuser with the requisite offset and viewing angles, which can be efficiently produced holographically. Another advantage relates to the copying procedure, which is simpler than direct recording using a predetermined diffuse

WO 02/10803

PCT/US01/41559

- 13 -

master, provided certain conditions are met. One of these conditions is that the peak wavelength of light diffracted from the master falls roughly into the center of the visible spectral range. Also the volume diffuser, which is used for copying, can have the proper angular spread to create an adequate viewing angle in the reflective mode.

5 A method of forming a structure like that of Fig. 7 from a volume hologram is shown in Fig. 9. In order to form such a structure we assume that (1) photoresist 22, is in intimate contact with the holographic diffuser 27, (2) beam 21 is incident from outside, passing through the photoresist and into the volume hologram, (3) beam 20 is reflected from the interference planes 28 within the volume hologram back through the photoresist layer and (4) 10 the index of refraction of the volume hologram has a typical value of $n = 1.5$. Thus copying is done with only a single beam.

In order to create beams 20 and 21 at angles of 49.56 degrees and 30.08 degrees (as shown in Fig. 7), these beams, denoted as 29 and 30 in Fig. 9, must have angles of 59.61 degrees and 34.61 degrees respectively in the lower index material 27 ($n = 1.5$). Such beams 15 exist in the volume reflective hologram 27 only if it contains fringe planes tilted at 12.5 degrees as shown in Fig. 9, and whose spacing $d = 216.28 \text{ nm}$. This assumes that the copy wavelength is 441.6 nm. Light incident normally onto these fringe planes will reconstruct coherently at a wavelength of $\lambda = 2nh = 2(1.5)(216.28) = 648.85 \text{ nm}$, which is red. This result points out a fundamental characteristic of this type of construction; namely, that 20 copying into a high index material at large incidence angles from a lower index master, requires that the master be red-shifted with respect to the copy. In other words, reconstruction of a blazed surface pattern producing light peaked in the green spectral region requires a master peaked in the red spectral region. Such a volume hologram can be easily made with a conventional holographic setup using red laser light (e.g., a Kr laser at 647 nm or a He-Ne 25 laser at 633 nm) and either red-sensitive photographic emulsion or photopolymer. It is also possible to copy from a photopolymer master diffuser that is already tuned to the green spectral region, provided that certain steps are made to convert the diffuser to the red region. For example, the green Polaroid Imagix diffuser photopolymer can be copied directly into a DuPont 706 photopolymer, using either green laser light at near normal incidence or blue 30 441.6 nm laser light at a large angle of incidence. The DuPont material can then be tuned to the red region using DuPont CTF color tuning film, which essentially swells the

WO 02/10803

- 14 -

photopolymer to a larger thickness, thereby increasing the spacing between the planes and changing the color from green to red.

Here again the angle for beam 20 in the photoresist is greater than the critical angle (49.56 > 36.03) and we must resort to coupling by means of a liquid gate. The photoresist plate is placed in a rectangular tank containing an index matching liquid for glass at $n \approx 1.5$ (e.g., xylene) that is liquid coupled to an equilateral prism, as shown in Fig. 9.

Variations of the methods disclosed here can result in efficient directional diffusers. For example, with the first type disclosed, uniform angular spreading of the incident beam may be accomplished by a variation of either the period p or the slope $\theta/2$ from sawtooth 10 element to sawtooth element. However, such a procedure may require that the element size p be reduced (for example from 100λ to 10 or 20λ) so as to preserve the smooth visual texture of the diffuser. If the size p is too large, visible portions of the diffuser will not scatter into the observation direction.

A variation of the holographic method discussed herein, is the addition of a fine 15 diffusing structure to a coarse wedge structure. This coarse wedge structure is of larger dimensions than that of the methods described in Figs. 7 and 8, and can be constructed in the following manner, as shown in Fig. 10. Two beams enter the photoresist layer 33 that is coated onto a glass substrate 34 from the same side 35 at an oblique angle, such that the interference fringe structure 36 is coarse and inclined at some angle with respect to the 20 surface. Prism coupling allows for a large degree of obliquity in a manner similar to that shown in Fig. 9.

A diffuse component can be added in a second exposure step by contacting the photoresist layer 33 to a reflective diffuser 39, as shown in Fig. 11. In this case the incident beam 37 is totally reflected as a diffuse beam 40 that encompasses a range of angles. The 25 contact can be done using either a liquid gate, or by reversing the plate and attaching the diffuser directly to the glass substrate and using a liquid gate between the photoresist and the prism. For this procedure to be effective, the resist should be coated to a several micron thick layer. The first exposure should be done at a laser wavelength for which absorption is large, for example 441.6 nm, so that the amount of reflected light is minimal. The second exposure 30 should be done at a longer, less absorbing wavelength, for example 457.9 or 476 nm, so that the reflected beam is nearly equal in intensity to the incident beam.

- An alternate technique adds a fine step structure to the coarse wedge of Fig. 10, in place of the fine diffusing structure. With this technique the second exposure uses two beams that enter the photoresist from opposite sides so that the interference fringe structure is fine and parallel to the surface. This is also done by prism coupling, using a single beam 37
5 that is totally reflected that interferes with itself, as shown in Fig. 12, with the fine fringe structure designated as 38. For this exposure the photoresist plate is reversed so that the surface 35 faces out. When the photoresist is developed after the composite exposure, the resulting structure is a deep wedge-shaped grating that has a fine stepped grating superimposed onto it (Fig. 13).
10 The diffraction efficiency for a ten-level structure is shown in Fig. 14 and includes the spectral distribution for diffracted orders +2, +1, 0, -1, and -2. Also included in this plot is the spectral distribution for a single-step blazed grating, which is identical to Fig. 5. It is clearly evident that the spectral distribution for the single-step shallow blazed grating forms an envelope for the ten-level deep stepped grating. The number of orders that appear under
15 this envelope decreases as the number of levels is reduced, but their individual spectral width increases.

As can be seen from Fig. 14, the diffraction is specularly discrete, allowing only narrow band color components to be observed at any given viewing angle. In order to avoid this often undesirable result, the photoresist can be exposed in narrow adjacent stripes that
20 yield, for example, red, blue, and green light diffracted at the same angle to produce white. The proper angle for light diffracted from the stepped grating structure is determined by the periodicity of the coarse wedge grating, and that periodicity depends, in turn, on the oblique angle that the interference fringe structure makes with respect to the photoresist surface.

Another variation on this method consists of first making a wedge grating structure of
25 large periodicity and adding the step structure or diffuse structure to it holographically. In this configuration, it is similar to the structure shown in Fig. 1c. For the step structure, the procedure consists of coating the wedge structure with a thin, uniform layer of photoresist, which can be done either by dip coating or by spin coating. The coated wedge surface is then immersed in an index-matching liquid gate that is optically contacted to an equilateral glass
30 prism, as described above. The step structure is made by exposing to a totally reflecting beam of laser light that is coupled to a diffuse surface, also described above. With this method many more diffracted orders are obtained than with the totally holographic method described

WO 02/10803

- 16 -

above, due to the much greater depth of the preformed structure compared to that obtained holographically, but with diffuse mixing the diffracted light appears white.

The discussion has focused on devices that uniformly scatter light through a solid angle. But in some applications it may be desirable to achieve non-uniform scattering. One
5 can modify the processes to create blazed diffusers that have a wide range of scattering properties.

Both categories of structures have been described in the foregoing in reference to their scattering properties in one dimension only. That is, the emphasis has been on showing how an incident beam whose obliquity to the surface (i.e., $\theta = 30^\circ$) is scattered uniformly
10 throughout an angle α , as in Fig. 1. But in the other direction, which follows the coordinate going into the paper in all of the Figs., the illumination beam 2 (See Fig. 1) is assumed to have no obliquity, but to impinge perpendicular to the surface. In order to obtain a uniform angular diffusion, there is a similar requirement for scattering over an angle of α in this dimension also, albeit without an offset θ . For the first category of diffuser described here,
15 the surface profile into the paper for the surface of Fig. 2 would contain the parabolic component, thus providing a diffuser, each portion of which scatters uniformly throughout a pyramidal solid angle which is offset from the incident illumination by angle θ . Similarly if a beam, which is randomly diffuse throughout a cone of angles, is reconstructed as beam 20 in Fig. 9 from the photopolymer hologram 27, the resulting aluminized diffuser will scatter
20 incoming light throughout a conical solid angle, offset by angle θ .

Having thus described at least one illustrative embodiment of the invention, various alterations, modifications and improvements will readily occur to those skilled in the art. Such alterations, modifications and improvements are intended to be within the scope and spirit of the invention. Accordingly, the foregoing description is by way of example only and
25 is not intended as limiting.

What is claimed is:

WO 02/10863

PCT/US01/41559

- 17 -

1. A directional reflector having a surface, the surface comprising:
 - a first periodic surface component having a periodic wedge-shape, the periodic wedge-shape having a first period, and
 - a second surface component.
- 5 2. The directional reflector of claim 1, wherein the surface is reflective.
3. The directional reflector of claim 1, wherein the surface is diffractive.
- 10 4. The directional reflector of claim 1, wherein the second surface component is periodic, the second surface component having a second period.
5. The directional reflector of claim 4, wherein the second period is equal to or less than the first period.
- 15 6. The directional reflector of claim 1, wherein the second surface component is superimposed over the first surface component.
7. The directional reflector of claim 1, wherein the second surface component
20 modifies the first surface component.
8. The directional reflector of claim 1, wherein the second surface component is random.
- 25 9. The directional reflector of claim 1, wherein the combination of the first periodic surface component and the second surface component cause an oblique light ray, which is incident on the surface, to be reflected throughout a range of angles.
10. The directional reflector of claim 9, wherein the range of angles is a cone of rays.
30
11. The directional reflector of claim 9, wherein the range of angles has a central ray and wherein the central ray is normal to the surface.

WO 02/10803

PCT/US01/41559

- 18 -

12. The directional reflector of claim 1, wherein the second periodic surface component includes a plurality of periodic surface pieces, wherein each periodic surface piece is described by a parabolic function and reflects an incident ray throughout a specified
5 uniform range of angles.

13. The directional reflector of claim 1, wherein the second surface component has a random roughness.

10 14. An apparatus having a surface, the surface having periodic surface elements comprising:

a first surface component in a first surface direction comprising two contiguous pieces, wherein a first surface piece is described by a parabolic function, and the second surface piece is described by an identical but inverted parabolic function;

15 a second surface component in a second surface direction, the second surface direction being orthogonal to the first surface direction, comprising two contiguous pieces wherein a third surface piece is described by an offset parabolic function, and a fourth surface piece is described by an identical but inverted offset parabolic function thereby creating a surface which is capable of transmitting or reflecting oblique incident light into a bundle of rays
20 which are uniformly distributed about a normal to its surface.

15. The apparatus of claim 14, wherein the parabolic function and the offset parabolic function are selected to create a surface free of discontinuities.

25 16. A method for making a directional reflector having a reflective surface, wherein the reflective surface includes at least one periodic surface comprising a plurality of periodic surface pieces and wherein the period surface pieces are each described by a parabolic function and reflect an incident ray throughout a specified uniform cone of angles, comprising the steps of:

30 creating a gray scale mask;
transmitting recording light through the gray scale mask such that a desired parabolic function is displayed; and

WO 02/10803

PCT/US01/41559

- 19 -

recording the desired parabolic function in a layer of photoresist.

17. The method for making a directional reflector having a reflective surface of claim 16, further comprising the step of coating a second periodic surface with the layer of 5 photoresist prior to recording the desired parabolic function.

18. The method for making a directional reflector having a reflective surface of claim 17, wherein the second periodic surface is wedge-shaped.

- 10 19. A method for making a directional reflector for reflecting an amount of incident light, the directional reflector having a reflective surface, wherein the reflective surface includes at least one periodic surface and wherein the periodicity of the at least one periodic surface is on the order of a wavelength of the incident light, comprising the step of holographically creating an off-axis diffuser in a volume recording material, wherein the off 15 axis diffuser is created using prism coupling and recording from the volume holographic diffuser into a surface relief diffuser.

- 20 20. The method for making a directional reflector having a reflective surface of claim 19, wherein the volume control medium is photoresist.

21. A method for making a directional reflector for reflecting an amount of incident light, the directional reflector having a reflective surface, wherein the reflective surface has a periodicity on the order of a wavelength of the incident light and wherein the reflective surface further includes a coarse periodicity having an asymmetrical blazed profile and a fine periodicity, comprising the steps of:

25 creating the coarse periodicity having an asymmetrical blazed profile by prism coupling and recording into a layer of photoresist using more than one beam, wherein each beam is separated by a small angle and wherein each beam is incident at a large oblique angle; and

30 creating the fine periodicity by reflecting a single beam from the layer of photoresist using prism coupling.

WO 02/10803

PCT/US01/41559

- 20 -

22. The method for making a directional reflector having a reflective surface of claim 21 further comprising the step of adding a diffuse component by having one beam be incident through the photoresist layer onto a predetermined diffuse reflector by means of prism coupling.

5

23. A method for obtaining white light using a directional reflector having a reflective surface, wherein the reflective surface has a periodicity on the order of a wavelength of incident light and wherein the reflective surface further includes a coarse periodicity having an asymmetrical blazed profile and a fine periodicity, comprising the steps of:

10 creating the coarse periodicity having an asymmetrical blazed profile by prism coupling and recording into a layer of photoresist using more than one beam, wherein each beam is separated by a small angle and wherein each beam is incident at a large oblique angle;

15 creating the fine periodicity by reflecting a single beam from the layer of photoresist using prism coupling; and

recording the fine periodicity in adjacent narrow parallel stripes, wherein each stripe reflects a different color.

24. A method for making a directional reflector having a reflective surface, the reflective surface comprising a first periodic surface component having a periodic wedge-shape, the periodic wedge-shape having a first period and a second periodic surface component, the second periodic surface component having a second period, wherein the combination of the first periodic surface component and the second periodic surface component cause an oblique light ray, which is incident on the reflective surface, to be reflected into a cone of rays, comprising the steps of:

25 mechanically ruling the wedge-shape;

creating a plastic replica from the mechanical ruling;

creating a random array of shallow parabolic depressions by spraying the plastic replica with a fine droplet spray containing a plastic solvent.

30

25. The method for making a directional reflector having a reflective surface of claim 24, further comprising the steps of:

WO 02/10803

PCT/US01/41559

- 21 -

creating a metal replica from the sprayed plastic replica;
creating a second plastic replica from the metal replica; and
spraying the second plastic replica with a fine droplet spray containing a plastic solvent.

5

26. The method for making a directional reflector having a reflective surface of claim 25 wherein the steps are repeated.
